ABSTRACT

Modern machine learning algorithms are often susceptible to adversarial examples — maliciously crafted inputs that are undetectable by humans but that fool the algorithm into producing undesirable behavior. In this work, we show that adversarial examples exist in natural language classification: we formalize the notion of an adversarial example in this setting and describe algorithms that construct such examples. Adversarial perturbations can be crafted for a wide range of tasks — including spam filtering, fake news detection, and sentiment analysis — and affect different models — convolutional and recurrent neural networks as well as linear classifiers to a lesser degree. Constructing an adversarial example involves replacing 10-30% of words in a sentence with synonyms that don't change its meaning. Up to 90% of input examples admit adversarial perturbations; furthermore, these perturbations retain a degree of transferability across models. Our findings demonstrate the existence of vulnerabilities in machine learning systems and hint at limitations in our understanding of classification algorithms.

1 INTRODUCTION

Modern machine learning algorithms are often susceptible to adversarial examples — maliciously crafted inputs that are undetectable by humans but that fool the algorithm into producing undesirable behavior. Adversarial examples arise in image classification (Szegedy et al., 2014), speech recognition (Carlini et al., 2016), reinforcement learning (Behzadan & Munir, 2017) and in other domains. The existence of adversarial inputs has obvious security implications and also reveals important shortcomings in our understanding of modern machine learning algorithms.

In this work, we study adversarial perturbations in the context of natural language, and show that common text classification algorithms are affected by adversarially crafted inputs. Our work formalizes the notion of an adversarial example in natural language classification and proposes algorithms for constructing such examples. We also investigate reasons that give rise to adversarial examples, and identify two distinct factors affecting the vulnerability of a model; the first originates in the embedding layer of a neural network classifier, while the second originates in the hidden layers.

Constructing adversarial inputs typically involves replacing 10-30% of words in a sentence with synonyms that don't change its original meaning. Our experiments suggest that such inputs can be consistently constructed across multiple domains — including spam classification, fake news detection, and sentiment analysis — and in different models — convolutional and recurrent neural networks as well as linear classifiers to a lesser degree. Up to 90% of input examples admit adversarial perturbations; furthermore, these perturbations retain a degree of transferability across models.

Our findings suggest the existence of vulnerabilities in text classification systems and hint at limitations in our understanding of these systems. More generally, our work highlights the need to further investigate adversarial inputs in natural language tasks as well as in classification problems over discrete inputs.

Task: Spam filtering. **Classifier:** LSTM. **Original label:** 100% Spam. **New label:** 89% Non-Spam.

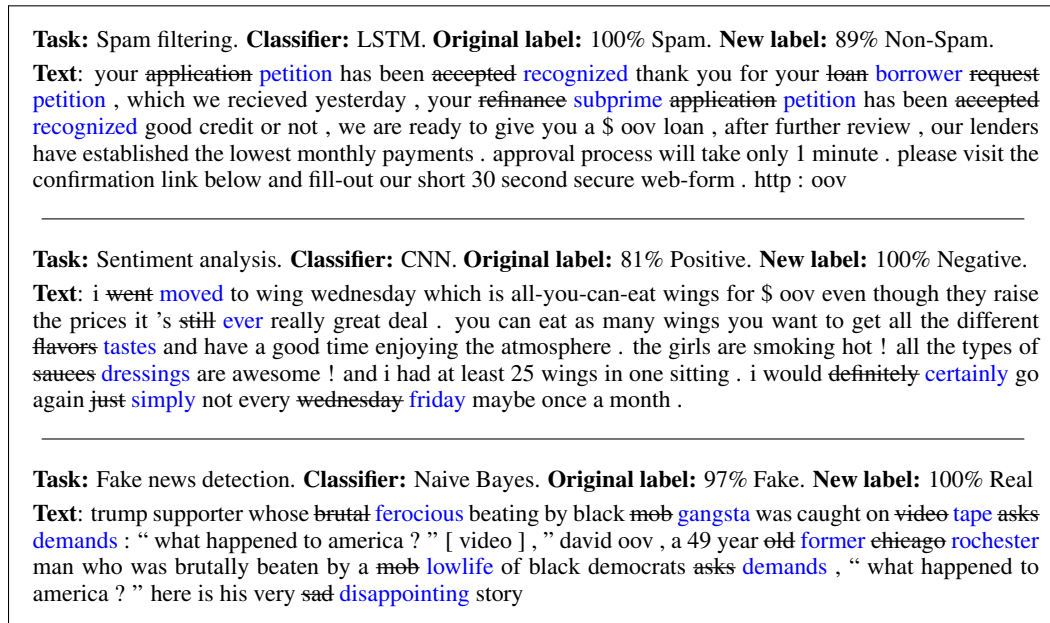

Figure 1: Adversarial examples for three natural language classification tasks. Replacing a fraction of the words in a document with adversarially-chosen synonyms fools classifiers into predicting an incorrect label. The new document is classified correctly by humans, and preserves most of the original meaning, although it contains small factual and grammatical errors.

2 BACKGROUND

We study classification problems, in which the goal is to learn a mapping $f : \mathcal{X} \to \mathcal{Y}$ from an input $x \in \mathcal{X}$ to a target label $y \in \mathcal{Y}$, which lies in some finite set of K classes $\mathcal{Y} = \{y_1, y_2, ..., y_K\}$. The classifier f associates a score $f_{y_k}(x)$ to each class y_k and outputs the class with the highest score. In this paper, f will be parametrized by a deep neural network or a linear model.

2.1 ADVERSARIAL EXAMPLES AND IMAGE CLASSIFICATION

Despite recent successes, modern classification algorithms based on deep neural networks are susceptible to adversarial examples (Szegedy et al., 2014), which are maliciously crafted inputs that are indistinguishable from real examples by humans, but that cause the algorithm to misbehave.

In the context of image classification, given a classifier f, we say that x' is an adversarial perturbation of x targeting class y' (distinct from the true class y of x) if

$$f(x') = y' \text{ and } \|x - x'\| \leq \epsilon. \tag{1}$$

The norm $\|\cdot\|$ captures the notion of an imperceptible perturbation; popular choices include the ℓ_2 or the ℓ_∞ norms. For simplicity, we refer to x' as an adversarial example for f.

Adversarial examples can be obtained by solving an optimization problem of the form

$$\max_{x'} J(x') \text{ s.t. } \|x - x'\| \leq \epsilon, \tag{2}$$

in which the objective $J(x')$ measures the extent to which x' is adversarial and may be a function of a target class $y' \neq y$, e.g. $J(x') = f_{y'}(x')$. Algorithms for solving the above objective include the Fast Gradient Sign method or iterative methods based on constrained gradient descent (Goodfellow et al., 2014; Papernot et al., 2016).

2.2 CLASSIFYING NATURAL LANGUAGE UTTERANCES

Text classification problems arise in varous domains, including biomedical (Aggarwal & Zhai, 2012), spam filtering (Androutsopoulos et al., 2000), and financial (Schumaker & Chen, 2009).

Linear classifiers with n-gram features often perform surprisingly well on text classification benchmarks (Wang & Manning, 2012). In recent years, variants of recurrent networks — especially classifiers based on long short-term memory (Hochreiter & Schmidhuber, 1997) — have helped improve state-of-the-art accuracy; most recently, convolutional neural networks have been shown to be competitive with recurrent methods (Kim, 2014; Zhang et al., 2015)

Natural language classification problems distinguish themselves from image classification by their discrete nature (the inputs x consist of discrete symbols such as characters or words) and by their higher dimensionality, which is typically proportional to vocabulary size. Furthermore, natural language representations are in a sense "higher-level" than image pixels, since they raw words encode significantly more meaning than raw pixel values. These differences pose natural constraints on the notion of an adversarial example, which our work explores.

3   ADVERSARIAL EXAMPLES FOR NATURAL LANGUAGE CLASSIFICATION

This work explores adversarial examples in the context of natural language classification. Defining adversarial inputs for text classifiers is complicated by two problems: first, there is no simple notion of metric between utterances (making it difficult to define an imperceptible perturbation); second, discrete inputs are not amenable to gradient-based methods and thus require new optimization algorithms.

In this section, we first propose a general notion of adversarial perturbation that applies to both continuous and discrete inputs. Then, we instantiate this notion in the context of language classification. Finally, we propose a general optimization algorithm for constructing adversarial inputs; the following section examines our approach experimentally.

3.1   ALTERED ADVERSARIAL EXAMPLES

A large class of adversarial inputs are formed by adding imperceptible perturbations to ordinary dataset samples. We propose to refer to this general type of adversarial attack as *altered* adversarial examples.

Given a classifier f, we say that x' is an adversarial alteration of x targeting class y' if

$$f(x') = y' \quad \text{and} \quad c(x, x') \leq \gamma, \tag{3}$$

for some domain-specific constraint function $c : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+^L$ and a vector of bounds $\gamma \in \mathbb{R}^L$ that capture the notion of imperceptible alteration via $L \geq 1$ constraints. For example, in the context of chemical molecules, we may use c to capture the edit distance between x and x' or the similarity of the molecules' three-dimensional structure. In the context of image classification, we recover the original notion of adversarial examples by taking c to be an ℓ_2 or ℓ_∞ norm constraint.

Our definition in contrast to other types of adversarial inputs explored in the literature. These include obfuscated examples (Carlini et al., 2016) — in which the input appears as white noise but triggers unwanted behavior (e.g., audio that turns on a smartphone) — and concatenative examples (Jia & Liang, 2017) — in which the input is combined with a distracting sequence that contains irrelevant information. Altered examples, on the other hand, encompass the original notion of adversarial perturbation, and apply in arguably more common settings, such as in classification.

3.2   ADVERSARIAL EXAMPLES FOR NATURAL LANGUAGE CLASSIFICATION

In a natural language context, we would intuitively like the altered examples x' to retain the same meaning as the original x .In some settings, it may also be sufficient to generate examples that humans and machines classify into different classes, without requiring that they exactly paraphrase the initial input.

To capture the above intuition, we propose to use a specially-crafted constraint function $c(x, x')$; the goal of this function is to ensure that both utterances share the same meaning and retain common syntactic properties (e.g. the style of writing should remain similar). Specifically, the function c is comprised on two constraints that capture sentence similarity on two levels.

Semantic similarity. We propose capturing the meaning of an utterance using the notion of a thought vector (Bengio et al., 2003; Mikolov et al., 2013). A thought vector can be seen as a mapping from sentences to a vector space, in which sentences with similar meanings are close to each other. In this context, our constraint is defined as

$$\|v - v'\|_2 < \gamma_1 \tag{4}$$

where v and v' are thought vectors associated with x and x', respectively, and γ_1 is a hyper-parameter.

There exist many ways of computing thought vectors for sentences, most of which will be compatible with our optimization algorithm. In the rest of the paper, we will restrict our attention to thought vectors that are averages of the vectors for individual words.

Syntactic similarity. Generally, thought vectors do not capture the syntactic validity of a sentence; for example, rearranging all the words in a sentence will produce the same word vector average. To ensure that adversarial sentences are well-formed, we introduce a syntactic constraint, which relies on a language model $P : \mathcal{X} \to [0, 1]$. Specifically, we require that the language model probability be similar between the perturbed and the original example.

$$|\log P(x') - \log P(x)| < \gamma_2 \tag{5}$$

We suggest training a language model on the same dataset as f; this allows the model to capture the extent to which x "looks like" a spam message or a movie review. We also require that the language model probabilities of x and x' be similar: thus if x is an ungrammatical sentence (i.e. a review uses incorrect English), then x' should retain a similar level of correctness.

3.3 GREEDY CONSTRUCTION OF ALTERED ADVERSARIAL EXAMPLES

Altered adversarial examples can be obtained by solving an optimization problem of the form

$$\max_{x'} J(x') \ \text{ s.t. } \ c(x, x') \le \gamma, \tag{6}$$

in which the objective $J(x')$ measures the extent to which x' is adversarial and may be a function of a target class $y' \neq y$, e.g. $J(x') = f_{y'}(x')$. We propose solving this optimization problem approximately using a greedy heuristic outlined as Algorithm 1.

In brief, we propose an iterative procedure that considers at each step all valid one-word changes to a sentence (i.e. which satisfy our constraints) and chooses the one that improves the objective the most. This procedure effectively replaces individual words with their synonyms, resulting in a new sentence of the same length that approximately preserves the original meaning.

Algorithm 1: Greedy Optimization Strategy for Finding Adversarial Examples

Data: Datapoint x, termination threshold τ, neighborhood size N, parameters $\gamma_1, \gamma_2, \delta$.
We initialize the algorithm at the uncorrupted data point: $x' \leftarrow x$;
while *Objective is below the threshold $J(x') < \tau$ and fraction of words replaced is less than δ* **do**
    Create a working set $W = \emptyset$;
    for *each word w in x* **do**
        for *each word $\bar{w}$ among the N closest to w and different from w* **do**
            substitute w' with $\bar{w}$ to get $\bar{x}$ and if $\bar{x}$ satisfies Equ. (5), then $W \leftarrow W \cup \{x'\}$;
    Choose highest scoring world replacement $x' \leftarrow \arg\max_{\bar{x} \in W} J(\bar{x})$ or if $W = \emptyset$, then **break** ;
return x';

Algorithm inputs. Algorithm 1 requires access to a target classifier f; it transforms x into x' by optimizing the objective J. We assume that x is a set of n discrete symbols called *words* and denoted by w_i for $i = 1, 2, ..., n$. Although we define our algorithm in the context of natural language, it easily extends to general discrete problems as well.

Optimization strategies. First, we place a bound δ on the fraction of words that can be substituted, i.e. $\sum_{i=1}^{n} \mathbb{I}\{w_i \neq w_i'\} \leq \delta \cdot n$; this enables us to "give up" on an example when it clearly does not admit an adversarial alteration. We also set a minimum threshold τ on the objective (e.g. the minimum desired score of the target label) and terminate when we reach it.

bad	delicious	enjoy
inclement	yummy	enjoying
mala	scrumptious	enjoys
naughty	appetizing	experience
rotten	tasty	savor
amiss	delectable	savoring

Table 1: Nearest neighbors in word vector space (Mrkšić et al., 2016).

Word replacement. We replace words with their nearest neighbors in a suitable word vector space, and consider the N closest neighbors. Thus, the neighbors are normally words that are likely to occur in the same context as the original word. To ensure that the replacements are also synonyms, we use the GloVE word vectors post-processed by with the method of Mrkšić et al. (2016); this ensures that the vectors satisfy linguistic constraints imposed by known synonym relations, and ensures that words with a similar meaning appear close to each other in the vector space (see Table 1).

4 EXPERIMENTS

4.1 TASKS

We study adversarial examples on three natural language classification tasks, summarized in Table 2. We held out 10% of the training set for validation; all adversarial examples are generated and evaluated on the test set. Likewise, we trained a trigram language model on the training set of each task and we instantiated the semantic constraint with the word vectors of Mrkšić et al. (2016). We describe our three classification tasks below.

Dataset	Task	#Train	#Test
Trec07p	Spam filtering	67.9k	7.5k
Yelp	Sentiment analysis	560k	38k
News	Fake news detection	5.3k	1.0k

Table 2: Summary of datasets and tasks

Spam filtering. The TREC 2007 Public Spam Corpus (*Trec07p*) contains 50,199 spam emails and 25,220 ham (non-spam) emails. We preprocess the data by removing all meta data and HTML tags. There is no standard split for this dataset, so we randomly pick 10% as a test set.

Sentiment analysis. The Yelp Review Polarity dataset (*Yelp*; Zhang et al., 2015) consists of almost 600,000 customer reviews from Yelp, covering primarily restaurant reviews. Each review is labeled as either positive or negative.

Fake news detection. The News dataset (McIntire, 2017) contains 6,336 articles scraped from online sources, and includes both real and fake news. Each article contains a headline and body text (which we concatenated before classification) and is associated with a binary label.

4.2 MODELS

We study adversarial example on a range of models that are widely used for classification; these include both linear classifiers and state-of-the-art deep learning algorithms.

Naive Bayes. This linear model has a long history in text classification and it is still popular for its simplicity. We convert each document into a bag-of-words representation, and following Wang & Manning (2012), we binarize the word features and use a multinomial model for classification.

Long short-term memory. Long-short term memory (LSTM; Hochreiter & Schmidhuber, 1997) is widely used in sequence modeling. We built a single-layer LSTM with 512 hidden units as in Zhang et al. (2015). The input to the LSTM is first transformed to a 300-dimensional vector using pretrained `word2vec` embeddings (Mikolov et al., 2013). We then average the outputs of the LSTM at each timestep to obtain a feature vector for a final logistic regression to predict the sentiment.

Shallow word-level convolutional networks. An alternative approach to text classification are convolutional neural networks (CNNs; Kim, 2014) We train a CNN with an embedding layer (as in the LSTM) a temporal convolutional layer, followed by max-pooling over time, and a fully connected layer for classification. We use a uniform filter size of 3 in each convolutional feature map; all other settings are identical to those of Kim (2014).

Deep character-level convolutional networks. We implement the character-level network of Conneau et al. (2016), which includes 4 stages. Each stage has 2 convolutional layers with batch normalization and 1 max-pooling layer; convolutional and pooling layers have strides of 1 and 2, respectively and filters of size 3. We start with 64 feature maps, and double the amount after each pooling step, concluding with k-max pooling layer with $k = 8$. The resulting activations in $\mathbb{R}^{4096}$ are classified by 3 fully connected layers.

4.3 MAIN EXPERIMENTS

Table 3 shows the accuracy of each classification model on the three datasets as well as on adversarial inputs generated using Algorithm 1. We manually selected the optimization settings that led to a reasonable tradeoff between the strength and the coherence of the adversarial examples. Specifically, in all experiments, we used a target of $\tau = 0.7$, a neighborhood size of $N = 15$, and parameters $\gamma_1 = 0.2$ and $\delta = 0.5$; we set the syntactic bound to $\gamma_2 = 2$ nats for sentiment analysis and fake news detection and $\gamma_2 = \infty$ for spam; spam messages were often malformed an the language model was no longer useful. We also compare against random perturbations obtained by replacing the $\arg\max$ in Algorithm 1 with random sampling.

Data		NB	LSTM	WCNN	VDCNN
	CLN	97.1%	99.1%	99.7%	
Trec07p	RND	97.7%	98.6%	99.6%	
	ADV	15.1%	39.8%	64.5%	
	CLN	87.9%	95.3%	94.9%	95.1%
Yelp	RND	86.8%	94.5%	94.7%	93.1%
	ADV	9.0%	24.0%	39.0%	53.0%
	CLN	91.0%	93.0%	96.0%	93.4%
News	RND	84.0%	94.6%	93.3%	92.7%
	ADV	9.0%	37.0%	71.0%	11.0%

Table 3: Classifier accuracy on each dataset. CLN, RND, and ADV stand for clean, randomly corrupted, and adversarially corrupted inputs, respectively.

All models are susceptible to adversarial examples to a certain degree, which depends in part on the task. Certain problems, such as spam filtering seem easier to classify and are less amenable to adversarial inputs; conversely, it is easier to fool the models on more difficult tasks, such as fake news detection. All methods are equally robust to random perturbations (just as image classifiers typically are), suggesting that adversarial inputs reside in very specific directions off the manifold of normal samples.

4.4 HUMAN EVALUATION

Input	Trec07p	Yelp	News
Original	87%	93%	64%
Adversarial	93%	87%	58%

Table 4: Human classification accuracy on adversarial examples for the LSTM model.

We verified the quality and the coherence of our examples via human experiments on Amazon Mechanical Turk. First, we subsampled a 100 random test set examples and asked human evaluators to assign labels (e.g. positive or negative review) to both the original data points, and their adversarially altered versions. We averaged the opinions of five different evaluations for each query. We found that human evaluators achieved similar accuracies on both types of inputs, suggesting that our adversarial alterations preserved key semantics sufficiently well to be recognized by a human. Human accuracy generally falls below that of the algorithms: the fake news task is inherently difficult, while non-spam email is often misclassified since there is no standard definition for "ham" emails; on sentiment analysis, both accuracies are within a reasonable margin of error.

Next, we asked human annotators to rate the "writing quality" of the same set of examples on a scale of one to five, with five being the highest possible quality and likely generated by a human,

and one being the lowest quality, likely generated by a machine. Table 5 shows that humans tend to assign similar scores to both sets of samples. Although our adversarial examples were not perfectly formed, these results suggest that they were of comparable quality to the original examples (which also contained multiple spelling and grammar errors).

4.5 ERROR ANALYSIS

We found that our adversarial examples exhibit three kinds of errors: syntactic, semantic, and factual. Syntactic errors are ungrammatical word substitutions; these include replacing "isis claim responsibility for shooting" with "isis petition responsibility for shooting" and "never before has an fbi director" to "never until has an fbi director"; the first error is due to multiple word meanings, while the latter is due to the words being unrelated (and far in word vector space).

Input	Trec07p	Yelp	News
Original	2.64	2.37	2.72
Adversarial	2.75	2.38	2.47

Table 5: Human classification accuracy on adversarial examples for the LSTM model.

Semantic errors arise when the meaning of a sentence is altered. Most often, this is due to multiple word senses — e.g., "isis claim responsibility for shooting" to "isis claim responsibility for filming" — or due to word embedding errors — e.g., "isis claim responsibility for ceasefire". Factual errors are a special case when the sentence becomes obviously false, e.g. when chainging "Monday, March 16" changed to "Thursday, March 16", or "FBI assistant director james kallstrom" to "Pentagon assistant director james kallstrom", or "republicans backing Trump" to "republicans backing Obama". These may not be an issue with fake reviews or fake news, and may be remedied via specialized techniques, e.g. by performing Named Entity Recognition.

4.6 TRANSFERABILITY

	NB	LSTM	WCNN	VDCNN
NB	20%	77%	75%	88%
LSTM	67%	17%	64%	83%
WCNN	63%	64%	17%	84%
VDCNN	77%	85%	87%	23%

Table 6: Transferability of adversarial examples on the Yelp dataset. Row i and column j show the accuracy of adversarial samples generated for model i evaluated on model j.

An intriguing property of image classification models is that adversarial examples generated for one classifier are likely to be misclassified by ther classifiers. We also examined whether adversarial texts transfer between the four models, focusing on the Yelp dataset. As seen in Table 6, there is a moderate degree of transferability between models. Interestingly, adversarial examples for three word level models (NB, LSTM, WCNN) do not generalize as well to the character level deep CNN as to other word level models, which suggests that the choice of input representation (character or word) is a factor that affects transferability.

4.7 EXPLAINING ADVERSARIAL EXAMPLES

We attribute the existence of adversarial examples to two factors, which we refer to as embedding-based and representation-based. A neural network classifier for text contains two stages: first, an embedding layer maps discrete words into continuous vectors; then, the embeddings are classified via convolutional or fully-connected layers.

Representation-based errors arise in the higher layers of the network; these layers are very similar to those of image classifiers and are therefore susceptible to the same types of attacks. In other words, by replacing a word, we may adversarially push the embedding representation off the learned manifold into an adversarial region, causing a mislabel. Representation-level adversarial perturbations have been studied by Miyato et al. (2017) in the context of adversarial training, and we observed them in our experiments as well.

On the other hand, embedding-based errors can be attributed to the inherently high dimensionality of the vocabulary, and can be studied by looking at linear classifiers. For example, a perturbation for Naive Bayes implies that words which we consider equivalent (e.g., definitely and certainly)

occur with different frequencies among the two classes. This, in turn, can happen for two reasons: firstly, since the vocabulary is large, such words will arise due to statistical noise, unless the dataset is also very large; secondly, two words may truly have different conditional class probabilities, either because of multiple meanings (e.g., awfully great deal and awfully bad) or because of hidden patterns that we don't understand (dogs are truly mentioned more often in spam than cats).

5 DISCUSSION

5.1 APPLICATIONS OF LANGUAGE-BASED ADVERSARIAL EXAMPLES

Our work demonstrates the existence of adversarial examples in state-of-the-art models for spam and sentiment classification (the fake news state-of-the-art is not yet established). The existence and transferability of such examples (obtained with very simple methods), hint at the existence of vulnerabilities in a number of systems; thes include text filtering systems (e.g., spam, racism), online ranking algorithms, speech command processors, and others. More generally, together with the work of Jia & Liang (2017), our observations lend further evidence to the prevalence of adversarial attacks in the natural language domain.

On the other hand, adversarial inputs can also improve algorithms via adversarial training (Shrivastava et al., 2016) by serving as extra data and thus increasing performance and robustness to adversarial attacks. Miyato et al. (2017) showed that adversarial perturbations to word embeddings are useful for semi-supervised learning; our findings hint at the possibility of adversarial training in the space of words.

5.2 COMPARISON TO OTHER DOMAINS

We found that adversarial examples are somewhat less abundant than in computer vision, especially on "easy" tasks such as spam classification. Interestingly, they affect linear models more; this smaller gap can be explained by the fact that text classification models are relatively shallow and word inputs are in a sense "higher-level" than pixels: they are more susceptible to perturbations and leave less work to the rest of the network. Although defining a metric between utterance is non-trivial, it is also somewhat more forgiving: in many domains (such as spam) grammatical errors are common, and the meaning does not get lost (or seem unnatural) with errors.

Finally, it's interesting to note that language-based problems have more direct access to the system being attacked; adversarial images are typically processed by real-world sensors, which affects their strength Kurakin et al. (2016); language-based examples are fed into the system directly, which could make them more potent.

5.3 FUTURE WORK

Our results demonstrate the existence of natural-language adversarial perturbations. However, our simple perturbations could be improved via a more sophisticated algorithm that takes advantage of language processing technologies, such as syntactic parsing, named entity recognition, or paraphrasing, or that could be assisted by humans. Furthermore, the existing search procedure naturally generalizes to beam search, and could modify phrases rather than words. Interesting extensions apply to character-based substitutions, targeting both word- and character-based systems.

6 CONCLUSION

We generalize the concept of adversarial examples to natural language classification by proposing a simple yet effective similarity metric for text. Then evaluate our approach on several classification tasks and show that a simple greedy algorithm is effective at finding adversarial examples in each setting.

The presence of adversarial examples for text classification poses threat to real-world machine learning systems. We further study of adversarial examples for text classification with help defend these systems and improve the accuracy of classification algorithms via adversarial training.
